Supplement

1 Heterogeneity analysis

The prediction interval and p-original values used for models and point estimates were done on the original scale where possible. However, to do heterogeneity analysis, our imputed value for tau is in SMD units, so we have to use SMD units for the original and replication values. This limits the number of applicable original-replication pairs. Prediction intervals are sensitive to whether only studies with SMD are included (different studies report differently and also vary in how close replications were) and whether the scale used was original or SMD (if the variances differed between original and replication).

Of all studies where prediction intervals can be calculated, 62/136 (46%) of the original estimates had prediction intervals that included the replication effect size. For those where we have SMD, 43/112 (38%) of the original estimates had prediction intervals that included the replication effect size, when we use original units where possible. Using SMD units, 33/112 (29%) of the original estimates had prediction intervals that included the replication effect size. Allowing for heterogeneity, with tau=.21, 72/112 (64%) of the original estimates are distributionally consistent.

2 Additional model results

Per our pre-registration, we ran a set of 6 models crossing 3 outcome measures (subjective replication score, whether the replication result was within the prediction interval of the original, and p-original on the hypothesis that both came from the same distribution) with 2 sets of predictors (with or without statistical predictors). These 6 models required 3 tiers of data: the subjective replication score without statistical predictors applies to all the data; the p_original and prediction interval models apply to the subset of data with numeric outcomes that can be compared; and the statistical predictor models need the smaller subset of data with p-values and original standardized effect size in particular.

Due to low sample sizes and large numbers of predictors, even with regularizing priors, the coefficient estimates generally have a lot of uncertainty.

2.1 Sensitivity Analysis

As a check on whether our results were sensitive to the inclusion of pairs that were marginal in some way, we repeated the 6 models including only studies that were not marginal. For sensitivity analyses, we completely excluded some studies where the replication analysis was not the focal analysis of the original (ex. student chose a manipulation check as their primary analysis). We also excluded studies with extremely small or lop-sided sample sizes.

For some studies that were included with some statistical outcomes in the main results, we downgraded them to experimental features only for sensitivity. Here, we felt the replication itself didn't have major problems and we felt confident in the subjective replication score reflecting holistically on the replication. However, there were some mismatches in the statistical reporting that meant we were not confident enough if your numeric calculations for the paper. Common mismatches were where one reported a t-test and the other reported mean and SDs, and when degrees of freedom seemed inconsistent across replication and original (suggesting different groupings or levels of analysis).
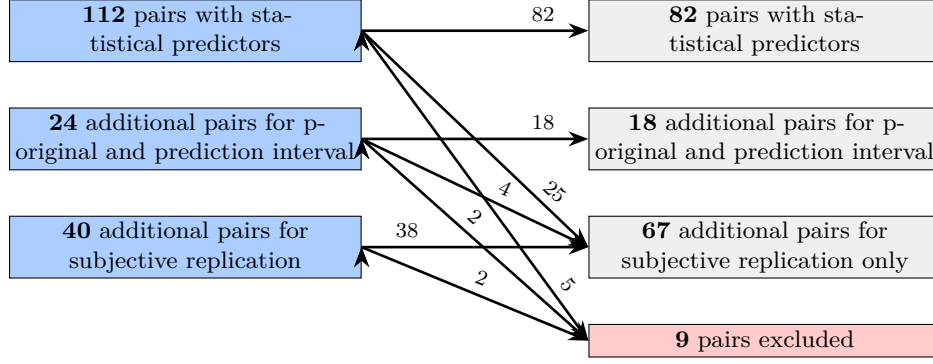

Figure 1: Diagram of what studies were downgraded or excluded for the sensitivity analysis.

Table 1: Odds ratios and 95% CrI from ordinal models predicting subjective replication scores. All pairs indicates that all pairs used, regardless of whether they had full statistical information; Full stats indicates that only pairs with full statistical information was used. Sensitivity indicates that it was a sensitivity test.

3   Sub sample of Psych Science papers

We were unable to use journal as a predictor in the models because of very uneven representation across journals. By far the most represented journal was Psychological Science, with 80 original papers. Other journals had at most a few papers in the sample.

Here we present bivariate analyses on the subset of the data coming from Psych Science. This is a post-hoc split of the data.

Table 2: Odds ratios and 95% CrI from logistic models predicting whether the prediction interval of the original effect contained the replication effect. All pairs indicates that all pairs with calculable prediction intervals were used, regardless of whether they had full statistical information; Full stats indicates that only data with full statistical information was used. Sensitivity indicates that it was a sensitivity test.
